1 Introduction

Limma is a package for the analysis of gene expression microarray data, especially the use of linear models for analysing designed experiments and the assessment of differential expression. Limma provides the ability to analyse comparisons between many RNA targets simultaneously. It has features which make the analyses stable even for experiments with small number of arrays—this is achieved by borrowing information across genes. The normalization and exploratory data analysis functions are for two-colour spotted microarrays. The linear model and differential expression functions apply to all microarrays including Affymetrix and other single-channel microarray experiments.

This guide gives a tutorial-style introduction to the main limma features but does not describe every feature of the package. A full description of the package is given by the individual function help documents available from the R online help system. To access the online help, type `help(package=limma)` at the R prompt or else start the html help system using `help.start()` or the Windows drop-down help menu.

The Bioconductor package `marray` provides alternative functions for reading and normalizing spotted microarray data. The `marray` package provides flexible location and scale normalization routines for log-ratios from two-color arrays. The `limma` package overlaps with `marray` in functionality but is based on a more general separation between within-array and between-array normalization. If you are using `limma` in conjunction with the `marray` package, see Section 10. The Bioconductor package `affy` provides functions for reading and normalizing Affymetrix microarray data. If you are using the `affy` package, see Section 7.2 and the relevant case studies.

This guide describes `limma` as a command-driven package. Packages `limmaGUI` and `afflimGUI` are also available which provides graphical user interfaces to the most commonly used functions in `limma` (Wettenhall and Smyth, 2004). Both packages are available from Bioconductor or from <http://bioinf.wehi.edu.au/limmaGUI>. The package `limmaGUI` is for use with two-color data while `afflimGUI` is for Affymetrix data.

This tutorial was prepared using R Version 2.0 for Windows and `limma` version 1.8.6.

Help with `limma` is available by sending questions or problems to the Bioconductor mailing list bioconductor@stat.math.ethz.ch.

2 Installation

`Limma` is a package for the R computing environment and it is assumed that you have already installed R. See the R project at <http://www.r-project.org>.

Installing from CRAN. `Limma` is available as a contributed package from the R Project CRAN site. This is the recommended repository from which to obtain `limma`. If you are using R on a system with a suitable internet connection and with installation privileges on your computer, you should be able to install it via

```
> install.packages("limma")
```

at the R prompt from an internet-connected computer. If you are using Windows, use the drop-down menu [Packages > Install package(s) from CRAN ...].

Installing from WEHI. The `limma` home page is <http://bioinf.wehi.edu.au/limma>. The latest version of the package is always available from this page, sometimes a few days ahead of the CRAN site. Unlike CRAN, this page supports only the latest release of R (not the developmental version) and does not provide a Mac package build. You should be able to install `limma` from this page using

```
> install.packages("limma", contriburl="http://bioinf.wehi.edu.au/limma")
```

at the R prompt.

Installing from Bioconductor. `Limma` is available as part of the Bioconductor project at <http://www.bioconductor.org>. Bioconductor works on a 6-monthly official release cycle, lagging each major R release by a few weeks. This means that Bioconductor software is updated only once every six months, unless you are using the developmental version R. Updates

of limma between the Bioconductor official releases should be obtained from one of the above two sites.

Change-log. Limma is updated frequently, often a couple of times a week. The change-log can be viewed at <http://bioinf.wehi.edu.au/limma/changelog.txt>. It can also be viewed from the R prompt. To see the most recent 20 lines type:

```
> changeLog(n=20)
```

3 A Few Preliminaries on R

R is a program for statistical computing. It is a command-driven language meaning that you have to type commands into it rather than pointing and clicking using a mouse. A good way to get started is to type

```
> help.start()
```

at the R prompt or, if you're using Windows, to follow the drop-down menu [Help > Html help]. Following the links [Packages > limma] from the html help page will lead you to the contents page of help topics for commands in limma.

Before you can use any limma commands you have to load the package by typing

```
> library(limma)
```

at the R prompt. You can get help on any function in any loaded package by typing `?` and the function name at the R prompt, for example

```
> ?read.maimages
```

for detailed help on the `read.maimages` function. Anything that you create in R is an “object”. Objects might include data sets, variables, functions, anything at all. For example

```
> x <- 2
```

will create a variable `x` and will assign it the value 2. At any stage of your R session you can type

```
> objects()
```

to get a list of all the objects you have created. You see show the contents of any object by typing the name of the object at the prompt, for example either of the following commands will print out the contents of `x`:

```
> show(x)
> x
```

We hope that you can use limma without having to spend a lot of time learning about the R language itself but a little knowledge in this direction will be very helpful, especially when you want to do something not explicitly provided for in limma or in the other Bioconductor packages. For more details about the R language see *An Introduction to R* which is available from the online help. For more background on using R for statistical analyses see Dalgaard (2002).

4 Quick Start

For those who want to see very quickly what a limma analysis might look like for cDNA data, here is a quick analysis of four replicate arrays (including two dye-swaps). The data has been scanned using an Axon scanner, producing a GenePix Array List (GAL) file, and then the intensities have been captured from the images using SPOT software. The GAL file and the image analysis files are in the current working directory of R. For more detail about the data see the Swirl Data example below.

```
# Read file containing info about the hybridizations,
# including names of files containing the intensity data
> targets <- readTargets("SwirlSample.txt")
# Read in the data
> RG <- read.maimages(targets$FileName, source="spot")
# Read in GAL file containing gene names, only needed if using SPOT!
> RG$genes <- readGAL()
# Set printer layout information
> RG$printer <- getLayout(RG$genes)
# Print-tip group loess normalization
> MA <- normalizeWithinArrays(RG)
# Scale normalization between arrays, optional
> MA <- normalizeBetweenArrays(MA)
# Estimate all the fold changes by fitting a linear model.
# The design matrix indicates which arrays are dye-swaps
> fit <- lmFit(MA, design=c(-1,1,-1,1))
# Apply Bayesian smoothing to the standard errors (very important!)
> fit <- eBayes(fit)
> options(digits=3)
# Show the top 30 genes, control false discovery rate
> topTable(fit, n=30, adjust="fdr")
```

5 Reading Data into Limma

This chapter is for two-color arrays. If you are using Affymetrix arrays, you should use the `affy` or `affyPLM` packages to read and normalize the data. If you have single channel arrays others than Affymetrix, you will need to read the intensity data into your R session yourself using the basic R read functions such as `read.table`. You will need to create a matrix containing the log-intensities with rows for probes and columns are arrays.

5.1 Recommended Files

We assume that an experiment has been conducted with one or more microarrays, all printed with the same library of probes. Each array has been scanned to produce a TIFF image. The TIFF images have then been processed using an image analysis program such as ArrayVision, ImaGene, GenePix, QuantArray or SPOT to acquire the red and green foreground and background intensities for each spot. The spot intensities have then been exported from the image analysis program into a series of text files. There should be one file for each array or, in the case of Imogene, two files for each array.

You will need to have the image analysis output files. In most cases these files will include the IDs and names of the probes and possibly other annotation information. A few image analysis programs, for example SPOT, do not write the probe IDs into the output files. In this case you will also need a *genelist* file which describes the probes. In most cases it is also desirable to have a *targets* file which describes which RNA sample was hybridized to each channel of each array. A further optional file is the *spot types* file which identifies special probes such as control spots.

5.2 The Targets Frame

The first step in preparing data for input into limma is usually to create a targets file which lists the RNA target hybridized to each channel of each array. It is normally in tab-delimited text format and should contain a row for each microarray in the experiment. The file can have any name but the default is `Targets.txt`. If it has the default name, it can be read into the R session using

```
> targets <- readTargets()
```

Once read into R, it becomes the *targets* frame.

The targets frame normally contains a FileName column, giving the name of the image-analysis output file, a Cy3 column giving the RNA type labelled with Cy3 dye for that slide and a Cy5 column giving the RNA type labelled with Cy5 dye for that slide. Other columns are optional. The targets file can be prepared using any text editor, but spreadsheet programs such as Microsoft Excel are convenient. The targets file for the Swirl case study includes optional SideNumber and Date columns:

	A	B	C	D	E	F
1	SlideNumber	FileName	Cy3	Cy5	Date	
2	81	swirl.1.spot	swirl	wild type	20/09/2001	
3	82	swirl.2.spot	wild type	swirl	20/09/2001	
4	93	swirl.3.spot	swirl	wild type	8/11/2001	
5	94	swirl.4.spot	wild type	swirl	8/11/2001	
6						

The targets file for the ApoAI case study includes a Name column which can be used to associate labels with the different arrays for plots and output:

	A	B	C	D	E	F	G
1	SlideNumber	Name	FileName	Cy3	Cy5		
2	1	c1	c1.spot	Ref	wild type		
3	2	c2	c2.spot	Ref	wild type		
4	3	c3	c3.spot	Ref	wild type		
5	4	c4	c4.spot	Ref	wild type		
6	5	c5	c5.spot	Ref	wild type		
7	6	c6	c6.spot	Ref	wild type		
8	7	c7	c7.spot	Ref	wild type		
9	8	c8	c8.spot	Ref	wild type		
10	9	k1	k1.spot	Ref	ApoAI KO		
11	10	k2	k2.spot	Ref	ApoAI KO		
12	11	k3	k3.spot	Ref	ApoAI KO		
13	12	k4	k4.spot	Ref	ApoAI KO		
14	13	k5	k5.spot	Ref	ApoAI KO		
15	14	k6	k6.spot	Ref	ApoAI KO		
16	15	k7	k7.spot	Ref	ApoAI KO		
17	16	k8	k8.spot	Ref	ApoAI KO		

For ImaGene files, the FileName column is split into a FileNameCy3 column and a FileNameCy5 because ImaGene stores red and green intensities in separate files. This is a short example:

	A	B	C	D	E	F
1	SlideNumber	FileNameCy3	FileNameCy5	Cy3	Cy5	
2	19	slide19w595.txt	slide19w685.txt	WT	Mutant	
3	20	slide20w595.txt	slide20w685.txt	Mutant	WT	
4						
5						

The targets file below was used to analyse the Scorecard spike-in controls for a particular experiment. Spike-in controls often need to be analyzed separately from other probes because there are only two different spike-in RNA samples, “Reference” and “Test”, whereas other probes may respond to any arbitrary number of RNA targets depending on the experiment. This means that, in a multi-array experiment, the spike-in control spots may not respond to the same design matrix as the other probes.

	A	B	C	D	E
1	SlideNumber	FileName	Cy3	Cy5	
2	2741	2741.spot	Test	Ref	
3	2742	2742.spot	Ref	Test	
4	2743	2743.spot	Test	Ref	
5	2744	2744.spot	Ref	Test	
6	2745	2745.spot	Test	Ref	
7	2747	2747.spot	Ref	Test	
8	2748	2748.spot	Test	Ref	
9	2749	2749.spot	Test	Ref	
10	2750	2750.spot	Test	Ref	
11					

5.3 Reading in Intensity Data

Let `files` be a character vector containing the names of the image analysis output files. The foreground and background intensities can be read into an `RGList` object using a command of the form

```
RG <- read.maimages(files, source="<imageanalysisprogram>", path="<directory>")
```

where `<imageanalysisprogram>` is the name of the image analysis program and `<directory>` is the full path of the directory containing the files. If the files are in the current R working directory then the argument `path` can be omitted; see the help entry for `setwd` for how to set the current working directory. The file names are usually read from the Targets File. For example, the Targets File `Targets.txt` is in the current working directory together with the SPOT output files, then one might use

```
> targets <- readTargets()
> RG <- read.maimages(targets$FileName, source="spot")
```

If the files are GenePix output files then they might be read using

```
> RG <- read.maimages(targets$FileName, source="genepix")
```

given an appropriate Targets File. Consult the help entry for `read.maimages` to see which other image analysis programs are supported. Files are assumed by default to be tab-delimited. If the files use a different separator this may be specified using the `sep=` argument. For example if the Genepix files were comma-separated (csv) then the read command would be

```
RG <- read.maimages(files, source="genepix", sep=",")
```

Reading data from ImaGene software is a little different to that of other image analysis programs because the red and green intensities are stored in separate files. This means that the targets frame should include two filename columns called, say, `FileNameCy3` and `FileNameCy5`, giving the names of the files containing the green and red intensities respectively. An example is given in Section 5.2. Typical code with ImaGene data might be

```
> targets <- readTargets()
> files <- targets[,c("FileNameCy3", "FileNameCy5")]
> RG <- read.maimages(files, source="imagene")
```

For ImaGene data, the `files` argument to `read.maimages()` is expected to be a 2-column matrix of filenames rather than a vector.

What should you do if your image analysis program is not currently supported by limma? If your output files are of a standard format, you can supply the column names corresponding to the intensities yourself. For example,

```
> RG <- read.maimages(files,
  columns=list(Rf="F635 Mean", Gf="F532 Mean", Rb="B635 Median", Gb="B532 Median"))
```

is exactly equivalent to the earlier command with `source="genepix"`. “Standard format” means here that there is a unique column name identifying each column of interest and that there are no lines in the file following the last line of data. Header information at the start of the file is ok.

It is a good idea to look at your data to check that it has been read in correctly. Type

```
> show(RG)
```

to see a print out the first few lines of data. Also try

```
> summary(RG$R)
```

to see a five-number summary of the red intensities for each array, and so on.

It is possible to read the data in several steps. If `RG1` and `RG2` are two data sets corresponding to different sets of arrays then

```
> RG <- cbind(RG1, RG2)
```

will combine them into one large data set. Data sets can also be subsetted. For example `RG[,1]` is the data for the first array while `RG[1:100,]` is the data on the first 100 genes.

5.4 Spot Quality Weights

It is desirable to use the image analysis to compute a weight for each spot between 0 and 1 which indicates the reliability of the acquired intensities at that spot. For example, if the SPOT image analysis program is used and the size of an ideal perfectly circular spot is known to be 100 pixels, then one might use

```
> RG <- read.maimages(files, source="spot", wt.fun=wtarea(100))
```

The function `wtarea(100)` gives full weight to spots with area 100 pixels and down-weights smaller and larger spots. Spots which have zero area or are more than twice the ideal size are given zero weight. This will create a component called `weights` in the RG list. The weights will be used automatically by functions such as `normalizeWithinArrays` which operate on the RG-list. With GenePix data

```
> RG <- read.maimages(files, source="genepix", wt.fun=wtflags(0.1))
```

will give weight 0.1 to any spot which receives a negative flag from the GenePix program.

The appropriate way to computing spot quality weights depends on the image analysis program that you are using. Consult the help entry `QualityWeights` to see what quality weight functions are available. The `wt.fun` argument is very flexible and allows you to construct your own weights. The `wt.fun` argument can be any function which takes a data set as argument and computes the desired weights. For example, if you wish to give zero weight to all GenePix flags less than -50 you could use

```
> myfun <- function(x) as.numeric(x$Flags > -50.5)
> RG <- read.maimages(files, source="genepix", wt.fun=myfun)
```

The `wt.fun` facility can be used to compute weights based on any number of columns in the image analysis files. For example, some researchers like to filter out spots if the foreground mean and median from GenePix for a given spot differ by more than a certain threshold, say 50. This could be achieved by

```
> myfun <- function(x, threshold=50) {
+   okred <- abs(x[, "F635 Median"] - x[, "F635 Mean"]) < threshold
+   okgreen <- abs(x[, "F532 Median"] - x[, "F532 Mean"]) < threshold
+   as.numeric(okgreen & okred)
+}
> RG <- read.maimages(files, source="genepix", wt.fun=myfun)
```

Then all the “bad” spots will get weight zero which, in limma, is equivalent to flagging them out. The definition of `myfun` here could be replaced with any other code to compute weights using the columns in the GenePix output files.

5.5 Reading the Gene List

In most cases the `RGList` read by `read.maimages()` will contain a component `RG$genes` containing the probe IDs and other probe-specific annotation. In some cases the `genes` component

will not be set because there is no probe information in the image analysis output files. An example is output from the SPOT program. In such cases, the probe information needs to be read separately.

If the arrays have been scanned with an Axon scanner, then the gene names will be available in a GenePix Array List (GAL) file. If the GAL file has extension “gal” and is in the current working directory, then it may be read into a data.frame by

```
> RG$genes <- readGAL()
```

Non-Genepix gene lists can be read into R using the function `read.table` from R base.

Once the gene array list is available, the print layout of the arrays can be extracted from it by

```
> RG$printer <- getLayout(RG$genes)
```

This will set the number of pins, or print-tips, using during the printing of the arrays. This determines the number of what are often called grids or meta rows and columns on the arrays. For ImaGene data, the print layout is already set automatically by `read.maimages` because this information, called “field dimensions” by ImaGene, is stored as part of the ImaGene output files.

5.6 The Spot Types File

The Spot Types file (STF) is another optional tab-delimited text file which allows you to identify different types of spots from the gene list. The STF is used to set the control status of each spot on the arrays so that plots may highlight different types of spots in an appropriate way. It is typically used to distinguish control spots from those corresponding to genes of interest and to distinguish positive from negative controls, ratio from calibration controls and so on. The STF should have a **SpotType** column giving the names of the different spot-types. One or more other columns should have the same names as columns in the gene list and should contain patterns or regular expressions sufficient to identify the spot-type. Any other columns are assumed to contain plotting attributes, such as colors or symbols, to be associated with the spot-types. This is one row for each spot-type to be distinguished.

The STF uses simplified regular expressions to match patterns. For example, **AA*** means any string starting with **AA**, ***AA** means any code ending with **AA**, **AA** means exactly these two letters, ***AA*** means any string containing **AA**, **AA.** means **AA** followed by exactly one other character and **AA\.** means exactly **AA** followed by a period and no other characters. For those familiar with regular expressions, any other regular expressions are allowed but the codes `^` for beginning of string and `$` for end of string should be excluded. Note that the patterns are matched sequentially from first to last, so more general patterns should be included first. The first row should specify the default spot-type and should have pattern `*` for all the pattern-matching columns.

Here is a short STF appropriate for the ApoAI data:

	A	B	C	D	E	F
1	SpotType	ID	Name	Color		
2	cDNA	*	*	black		
3	BLANK	BLANK	*	brown		
4	Blank	Blank	*	orange		
5	Control	Control	*	blue		
6						
7						
8						
9						

In this example, the columns ID and Name are found in the gene-list and contain patterns to match. The asterisks are wildcards which can represent anything. Be careful to use upper or lower case as appropriate and don't insert any extra spaces. The remaining column gives colors to be associated with the different types of points.

Here is a STF below appropriate for arrays with Lucidea Universal ScoreCard control spots.

	A	B	C	D	E	F
1	SpotType	ID	Name	Color		
2	gene	*	*	black		
3	ratio	*	Ratio*	red		
4	calibration	*	Calibr*	blue		
5	utility	*	Utility*	pink		
6	negative	*	Negative*	brown		
7	buffer	*	Buffer	orange		
8	blank	blank	*	yellow		
9						

If the STF has default name `SpotTypes.txt` then it can be read using

```
> spottypes <- readSpotTypes()
```

It is typically used as an argument to the `controlStatus()` function to set the status of each spot on the array, for example

```
> RG$genes$Status <- controlStatus(spottypes, RG)
```

6 Data Exploration

It is advisable to display your data in various ways as a quality check and to check for unexpected effects. We recommend an imageplot of the raw log-ratios and an MA-plot of the raw data for each array as a minimum routine displays. See the Swirl case study for some examples. The functions `imageplot3by2` and `plotMA3by2` can be used to automate the production of plots for all arrays in an experiment.

The following is an example MA-Plot for an Incyte array with various spike-in and other controls. (Data courtesy of Rebecca McCracken and Steve Gerondakis, Walter and Eliza Hall Institute of Medical Research.) The plot was produced using

```
> spottypes <- readSpotTypes()
> RG$genes$Status <- controlStatus(spottypes, RG)
> plotMA(RG)
```

The array includes spike-in ratio controls which are 3-fold, 10-fold and 25-fold up and down regulated, as well as non-differentially expressed sensitivity controls and negative controls.

7 Normalization

Limma implements a range of normalization methods for spotted microarrays. Smyth and Speed (2003) describe some of the mostly commonly used methods. The methods may be broadly classified into methods which normalize the M-values for each array separately (within-array normalization) and methods which normalize intensities or log-ratios to be comparable across arrays (between-array normalization). This section discusses mainly within-array normalization. Between-array normalization is discussed further in Section 15.

Print-tip loess normalization (Yang et al, 2001) is the default normalization method and can be performed by

```
> MA <- normalizeWithinArrays(RG)
```

There are some notable cases in which this is not appropriate. For example, Agilent arrays do not have print-tip groups, so one should use global loess normalization instead:

```
> MA <- normalizeWithinArrays(RG, method="loess")
```

Print-tip loess is also unreliable for small arrays with less than, say, 150 spots per print-tip group. Arrays with are larger than this may behave as small arrays if the number of spots with non-missing M-values is small for one or more of the print-tip groups. In these cases one should either use global "loess" normalization or else use robust spline normalization

```
> MA <- normalizeWithinArrays(RG, method="robustspline")
```

which is an empirical Bayes compromise between print-tip and global loess normalization, with 5-parameter regression splines used in place of the loess curves.

Loess normalization assumes that the bulk of the probes on the array are not differentially expressed. It not assumed that that differential expression is symmetric about zero, provided that the loess fit is implemented in a robust fashion, but it is necessary that there be a substantial body of probes which do not change expression levels. This assumption can be suspect for boutique arrays where the total number of unique genes on the array is small, say less than 150, particularly if these genes have been selected for being specifically expressed in one of the RNA sources. In such a situation, the best strategy is to include on the arrays a series of non-differentially expressed control spots, such as a titration series of whole-library-pool spots, and to use the up-weighting method discussed belwo. In the absence of the such control spots, normalization of boutique arrays requires specialist advice.

Any spot quality weights found in `RG` will be used in the normalization by default. This means for example that spots with zero weight (flagged out) will not influence the normalization of other spots. The use of spot quality weights will not however result in any spots being removed from the data object. Even spots with zero weight will be normalized and will appear in the output object, such spots will simply not have any influence on the other spots. If you do not wish the spot quality weights to be used in the normalization, their use can be over-ridden using

```
> MA <- normalizeWithinArrays(RG, weights=NULL)
```

The output object `MA` will still contain any spot quality weights found in `RG`, but these weights will not be used in the normalization step.

It is often useful to make use of control spots to assist the normalization process. For example, if the arrays contain a series of spots which are known in advance to be non-differentially expressed, these spots can be given more weight in the normalization process. Spots which are known in advance to be differentially expressed can be down-weighted. Suppose for example that the `controlStatus()` has been used to identify spike-in spots which are differentially expressed and a titration series of whole-library-pool spots which should not be differentially expressed. Then one might use

```
> w <- modifyWeights(RG$weights, RG$genes$Status, c("spikein","titration"), c(0,2))
> MA <- normalizeWithinArrays(RG, weights=w)
```

to give zero weight to the spike-in spots and double weight to the titration spots. The idea of up-weighting the titration spots is in the same spirit as the composite normalization method proposed by Yang et al (2002) but is more flexible and generally applicable. The above code assumes that `RG` already contains spot quality weights. If not, one could use

```
> w <- modifyWeights(array(1,dim(RG)), RG$genes$Status, c("spikein","titration"), c(0,2))
> MA <- normalizeWithinArrays(RG, weights=w)
```

instead.

Limma contains some more sophisticated normalization methods. In particular, some between-array normalization methods are discussed in Section 15 of this guide.

8 Background Correction

The default background correction action is to subtract the background intensity from the foreground intensity for each spot. If the `RGList` object has not already been background corrected, then `normalizeWithinArrays` will do this by default. Hence

```
> MA <- normalizeWithinArrays(RG)
```

is equivalent to

```
> RGb <- backgroundCorrect(RG, method="subtract")
> MA <- normalizeWithinArrays(RGb)
```

However there are many other background correction options which may be preferable in certain situations.

For the purpose of assessing differential expression, we often find

```
> RG <- backgroundCorrect(RG, method="normexp", offset=50)
```

to be preferable to the simple background subtraction with most image analysis programs. This method adjusts the foreground adaptively for the background intensities and results in strictly positive adjusted intensities, i.e., negative or zero corrected intensities are avoided. The use of an offset damps the variation of the log-ratios for very low intensities spots towards zero.

To illustrate some differences between the different background correction methods we consider one cDNA array which was self-self hybridized, i.e., the same RNA source was hybridized to both channels. For this array there is no actual differential expression. The array was printed with a human 10.5k library and hybridized with Jurkatt RNA on both channels. (Data courtesy Andrew Holloway and Dileepa Diyagama, Peter MacCallum Cancer Centre, Melbourne.) The array included a selection of control spots which are highlighted on the plots. Of particular interest are the spike-in ratio controls which should show up and down fold changes of 3 and 10. The first plot displays data acquired with GenePix software and background corrected by subtracting the median local background, which is the default with GenePix data. The plot shows the typical wedge shape with fanning of the M-values at low intensities. The range of observed M-values dominates the spike-in ratio controls. There are also 1148 spots not shown on the plot because the background corrected intensities were zero or negative.

The second plot shows the same array background corrected with `method="normexp"` and `offset=50`. The spike-in ratio controls now stand out clearly from the range of the M-values. All spots on the array are shown on the plot because there are now no missing M-values.

The third plot shows the same array quantified with SPOT software and with “morph” background subtracted. This background estimator produces a similar effect to that with `normexp`.

The effect of using “morph” background or using `method="normexp"` with an offset is to stabilize the variability of the M-values as a function of intensity. The empirical Bayes methods implemented in the limma package for assessing differential expression will yield most benefit when the variabilities are as homogenous as possible between genes. This can best be achieved by reducing the dependence of variability on intensity as far as possible.

9 Linear Models

9.1 Introduction

The package limma uses an approach called *linear models* to analyse designed microarray experiments. This approach allows very general experiments to be analysed just as easily as a simple replicated experiment. The approach is outlined in Smyth (2004) and Yang and Speed (2002). The approach requires one or two matrices to be specified. The first is the *design matrix* which indicates in effect which RNA samples have been applied to each array. The second is the *contrast matrix* which specifies which comparisons you would like to make between the RNA samples. For very simple experiments, you may not need to specify the contrast matrix.

The philosophy of the approach is as follows. You have to start by fitting a linear model to your data which fully models the systematic part of your data. The model is specified by the design matrix. Each row of the design matrix corresponds to an array in your experiment and each column corresponds to a coefficient which is used to describe the RNA sources in your experiment. With Affymetrix or single-channel data, or with two-color with a common reference, you will need as many coefficients as you have distinct RNA sources, no more and no less. With direct-design two-color data you will need one fewer coefficient than you have distinct RNA sources, unless you wish to estimate a dye-effect for each gene, in which case the number of RNA sources and the number of coefficients will be the same. Any set of independent coefficients will do, providing they describe all your treatments. The main

purpose of this step is to estimate the variability in the data, hence the systematic part needs to be modelled so it can be distinguished from random variation.

In practice the requirement to have exactly as many coefficients as RNA sources is too restrictive in terms of questions you might want to answer. You might be interested in more or fewer comparisons between the RNA source. Hence the contrasts step is provided so that you can take the initial coefficients and compare them in as many ways as you want to answer any questions you might have, regardless of how many or how few these might be.

If you have data from Affymetrix experiments, from single-channel spotted microarrays or from spotted microarrays using a common reference, then linear modeling is the same as ordinary analysis of variance or multiple regression except that a model is fitted for every gene. With data of this type you can create design matrices as one would do for ordinary modeling with univariate data. If you have data from spotted microarrays using a direct design, i.e., a connected design with no common reference, then the linear modeling approach is very powerful but the creation of the design matrix may require more statistical knowledge.

For statistical analysis and assessing differential expression, limma uses an empirical Bayes method to moderate the standard errors of the estimated log-fold changes. This results in more stable inference and improved power, especially for experiments with small numbers of arrays (Smyth, 2004). For arrays with within-array replicate spots, limma uses a pooled correlation method to make full use of the duplicate spots (Smyth et al, 2003).

9.2 Affymetrix and Other Single-Channel Designs

Affymetrix data will usually be normalized using the `affy` package. We will assume here that the data is available as an `exprSet` object called `eset`. Such an object will have a slot containing the log-expression values for each gene on each array which can be extracted using `exprs(eset)`. Affymetrix and other single-channel microarray data may be analysed very much like ordinary linear models or anova models. The difference with microarray data is that it is almost always necessary to extract particular contrasts of interest and so the standard parametrizations provided for factors in R are not usually adequate.

There are many ways to approach the analysis of a complex experiment in limma. A straightforward strategy is to set up the simplest possible design matrix and then to extract from the fit the contrasts of interest.

Suppose that there are three RNA sources to be compared. Suppose that the first three arrays are hybridized with RNA1, the next two with RNA2 and the next three with RNA3. Suppose that all pair-wise comparisons between the RNA sources are of interest. We assume that the data has been normalized and stored in an `exprSet` object, for example by

```
> data <- ReadAffy()
> eset <- rma(data)
```

An appropriate design matrix can be created and a linear model fitted using

```
> design <- model.matrix(~ -1+factor(c(1,1,1,2,2,3,3,3)))
> colnames(design) <- c("group1", "group2", "group3")
> fit <- lmFit(eset, design)
```

To make all pair-wise comparisons between the three groups the appropriate contrast matrix can be created by

```
> contrast.matrix <- makeContrasts(group2-group1, group3-group2, group3-group1, levels=design)
> fit2 <- contrasts.fit(fit, contrast.matrix)
> fit2 <- eBayes(fit2)
```

A list of top genes differential expressed in group2 versus group1 can be obtained from

```
> topTable(fit2, coef=1, adjust="fdr")
```

The outcome of each hypothesis test can be assigned using

```
> results <- decideTests(fit2)
```

A Venn diagram showing numbers of genes significant in each comparison can be obtained from

```
> vennDiagram(results)
```

9.3 Common Reference Designs

Now consider two-color microarray experiments in which a common reference has been used on all the arrays. Such experiments can be analysed very similarly to Affymetrix experiments except that allowance must be made for dye-swaps. The simplest method is to setup the design matrix using the `modelMatrix()` function and the targets file. As an example, we consider part of an experiment conducted by Joëlle Michaud, Catherine Carmichael and Dr Hamish Scott at the Walter and Eliza Hall Institute to compare the effects of transcription factors in a human cell line. The targets file is as follows:

```
> targets <- readTargets("runxtargets.txt")
> targets
```

	SlideNumber	Cy3	Cy5
1	2144	EGFP	AML1
2	2145	EGFP	AML1
3	2146	AML1	EGFP
4	2147	EGFP	AML1.CBFb
5	2148	EGFP	AML1.CBFb
6	2149	AML1.CBFb	EGFP
7	2158	EGFP	CBFb
8	2159	CBFb	EGFP
9	2160	EGFP	AML1.CBFb
10	2161	AML1.CBFb	EGFP
11	2162	EGFP	AML1.CBFb
12	2163	AML1.CBFb	EGFP
13	2166	EGFP	CBFb
14	2167	CBFb	EGFP

In the experiment, green fluorescent protein (EGFP) has been used as a common reference. An adenovirus system was used to transport various transcription factors into the nuclei of HeLa cells. Here we consider the transcription factors AML1, CBFbeta or both. A simple design matrix was formed and a linear model fit:

```

> design <- modelMatrix(targets,ref="EGFP")
> design
      AML1 AML1.CBFb CBFb
1      1      0      0
2      1      0      0
3     -1      0      0
4      0      1      0
5      0      1      0
6      0     -1      0
7      0      0      1
8      0      0     -1
9      0      1      0
10     0     -1      0
11     0      1      0
12     0     -1      0
13     0      0      1
14     0      0     -1
> fit <- lmFit(RG, design)

```

It is of interest to compare each of the transcription factors to EGFP and also to compare the combination transcription factor with AML1 and CBFb individually. An appropriate contrast matrix was formed as follows:

```

> contrast.matrix <- makeContrasts(AML1,CBFb,AML1.CBFb,AML1.CBFb-AML1,AML1.CBFb-CBFb,
+   levels=design)
> contrast.matrix
      AML1 CBFb AML1.CBFb AML1.CBFb - AML1 AML1.CBFb - CBFb
AML1      1      0      0      -1      0
AML1.CBFb 0      0      1      1      1
CBFb      0      1      0      0     -1

```

The linear model fit can now be expanded and empirical Bayes statistics computed:

```

> fit2 <- contrasts.fit(fit, contrasts.matrix)
> fit2 <- eBayes(fit2)

```

9.4 Direct Two-Color Designs

Two-colour designs without a common reference require the most statistical knowledge to choose the appropriate design matrix. A direct design is one in which there is no single RNA source which is hybridized to every array. As an example, we consider an experiment conducted by Dr Mireille Lahoud at the Walter and Eliza Hall Institute to compare gene expression in three different populations of dendritic cells (DC).

Arrow heads represent Cy5, i.e. arrows point in the Cy3 to Cy5 direction.

This experiment involved six cDNA microarrays in three dye-swap pairs, with each pair used to compare two DC types. The design is shown diagrammatically above. The targets file was as follows:

```

> targets
  SlideNumber   FileName Cy3 Cy5
1           12 ml12med.spot CD4 CD8
2           13 ml13med.spot CD8 CD4
3           14 ml14med.spot  DN CD8
4           15 ml15med.spot CD8  DN
5           16 ml16med.spot CD4  DN
6           17 ml17med.spot  DN CD4

```

There are many valid choices for a design matrix for such an experiment and no single correct choice. We chose to setup the design matrix as follows:

```

> design <- cbind("CD8-CD4"=c(1,-1,1,-1,0,0),"DN-CD4"=c(0,0,-1,1,1,-1))
> rownames(design) <- removeExt(targets$FileName)
> design

```

	CD8-CD4	DN-CD4
ml12med	1	0
ml13med	-1	0
ml14med	1	-1
ml15med	-1	1
ml16med	0	1
ml17med	0	-1

In this design matrix, the CD8 and DN populations have been compared back to the CD4 population. The coefficients estimated by the linear model will correspond to the log-ratios of CD8 vs CD4 (first column) and DN vs CD4 (second column). After appropriate normalization of the expression data, a linear model was fit using

```

> fit <- lmFit(MA, design, ndups=2)

```

The use of `ndups` is to specify that the arrays contained duplicates of each gene, see Section ??.

The linear model can now be interrogated to answer any questions of interest. For this experiment it was of interest to make all pairwise comparisons between the three DC populations. This was accomplished using the contrast matrix

```
> contrast.matrix <- cbind("CD8-CD4"=c(1,0), "DN-CD4"=c(0,1), "CD8-DN"=c(1,-1))
> rownames(contrast.matrix) <- colnames(design)
> contrast.matrix
      CD8-CD4 DN-CD4 CD8-DN
CD8-CD4      1      0      1
DN-CD4       0      1     -1
```

The contrast matrix can be used to expand the linear model fit and then to compute empirical Bayes statistics:

```
> fit2 <- constrast.fit(fit, contrast.matrix)
> fit2 <- eBayes(fit2)
```

10 Special Designs

10.1 Simple Comparisons

The simplest possible microarray experiment is one with a series of replicate two-color arrays all comparing the same two RNA sources. For a three-array experiment comparing wild type (wt) and mutant (mu) RNA, the targets file might contain the following entries:

FileName	Cy3	Cy5
File1	wt	mu
File2	wt	mu
File3	wt	mu

A list of differentially expressed genes might be found for this experiment by

```
> fit <- lmFit(MA)
> fit <- eBayes(fit)
> topTable(fit, adjust="fdr")
```

where `MA` holds the normalized data. The default design matrix used here is just a single column of ones. The experiment here measures the fold change of mutant over wild type. Genes which have positive M-values are more highly expressed in the mutant RNA while genes with negative M-values are more highly expressed in the wild type. The analysis is analogous to the classical single-sample *t*-test except that we have used empirical Bayes methods to borrow information between genes.

10.2 Dye Swaps

A simple modification of the above experiment would be to swap the dyes for one of the arrays. The targets file might now be

FileName	Cy3	Cy5
File1	wt	mu
File2	mu	wt
File3	wt	mu

Now the analysis would be

```
> design <- c(1,-1,1)
> fit <- lmFit(MA, design)
> fit <- eBayes(fit)
> topTable(fit, adjust="fdr")
```

Alternatively the design matrix could be set, replacing the first of the above code lines, by

```
> design <- modelMatrix(targets, ref="wt")
```

where `targets` is the data frame holding the targets file information.

If there are at least two arrays with each dye-orientation, it may be useful to estimate and the probe-specific dye effects. The dye-effect is estimated by an intercept term. If the experiment was

FileName	Cy3	Cy5
File1	wt	mu
File2	mu	wt
File3	wt	mu
File4	mu	wt

then we could set

```
> design <- cbind(DyeEffect=1,MUvsWT=c(1,-1,1,-1))
> fit <- lmFit(MA, design)
> fit <- eBayes(fit)
```

Now a list of differentially expressed genes would be obtained by

```
> topTable(fit, coef="MUvsWT", adjust="fdr")
```

The genes which show dye effects could be seen by

```
> topTable(fit, coef="DyeEffect", adjust="fdr")
```

Including the dye-effect in the model in this way uses up one degree of freedom which might otherwise be used to estimate the residual variability, but may be valuable if many genes show non-negligible dye-effects.

10.3 Technical Replication I

In the previous sections we have assumed that all arrays are biological replicates. Now consider an experiment in which two wild type and two mutant mice are compared using two arrays for each pair of mice. The targets might be

FileName	Cy3	Cy5
File1	wt1	mu1
File2	wt1	mu1
File3	wt2	mu2
File4	wt2	mu2

The first and second and third and fourth arrays are *technical replicates*. It would not be correct to treat these as four replicate arrays because the technical replicate pairs are not independent. If there are any differences between two wild type or two mutant mice then the technical replicate pairs are likely to be positively correlated.

One way to analyze these data is the following:

```
> corfit <- duplicateCorrelation(MA, ndups=1, block=c(1,1,2,2))
> fit <- lmFit(MA, block=c(1,1,2,2), correlation=corfit$consensus)
> fit <- eBayes(fit)
> topTable(fit, adjust="fdr")
```

The argument `block` indicates the two blocks corresponding to biological replicates. The value `corfit$consensus` measures the average correlation within the blocks and should be positive. (If `corfit$consensus` is negative, then the above method should not be used. In that case the technical replicate structure can be ignored, meaning that the data can be analyzed as if all arrays were biological replicates.) This analysis is analogous to *mixed model* analysis of variance (Milliken and Johnson, 1992, Chapter 18) except that information has been borrowed between genes. Information is borrowed (i) by constraining the within-block correlations to be equal between genes and (ii) by using empirical Bayes methods to moderate the standard deviations between genes.

If the technical replicates were in dye-swap pairs as

FileName	Cy3	Cy5
File1	wt1	mu1
File2	mu1	wt1
File3	wt2	mu2
File4	mu2	wt2

then one might use

```
> design <- c(1,-1,1,-1)
> corfit <- duplicateCorrelation(MA, design, ndups=1, block=c(1,1,2,2))
> fit <- lmFit(MA, design, block=c(1,1,2,2), correlation=corfit$consensus)
> fit <- eBayes(fit)
> topTable(fit, adjust="fdr")
```

In this case the correlation `corfit$consensus` should be negative, because the technical replicates are dye-swaps and should vary in opposite directions.

This method of handling technical replication using `duplicateCorrelation()` is somewhat limited. If for example one technical replicate was dye-swapped and other not,

FileName	Cy3	Cy5
File1	wt1	mu1
File2	mu1	wt1
File3	wt2	mu2
File4	wt2	mu2

then there is no way to use `duplicateCorrelation()` because the technical replicate correlation will be negative for the first pair but positive for the second.

10.4 Technical Replication II

In the last example of the previous section, it was noted that `duplicateCorrelation()` could not be used. An alternative is to include a coefficient for mouse in the linear model, i.e., to fit a separate effect for each mouse. This could be accomplished by defining

```
> design <- designMatrix(targets, ref="wt1")
> fit <- lmFit(MA, design)
```

This will fit a linear model with three coefficients,

```
> colnames(fit)

[1] "mu1" "mu2" "wt2"
```

which measure differences between the other mice and wt1. The coefficient `mu1` measures the difference between mouse `mu1` and mouse `wt1`. Coefficient `mu2` measures the difference between `mu2` and `wt1`. Coefficient `wt2` measures the difference between `wt2` and `wt1`. What we want is the average difference between the mutant and wild type mice, and this is extracted by the contrast $(\text{mu1} + \text{mu2} - \text{wt2})/2$:

```
> cont.matrix <- makeContrasts(MUvsWT=(mu1+mu2-wt2)/2, levels=design)
> fit2 <- contrasts.fit(fit, cont.matrix)
> fit2 <- eBayes(fit2)
> topTable(fit2, adjust="fdr")
```

This technique of including an effect for each biological replicate, in this case each mouse, is well suited to situations with a lot of technical replication. Here is a larger example from a real experiment. Three mutant mice are to be compared with three wild type mice. Eighteen two-color arrays were used with each mouse appearing on six different arrays:

```
> targets

      FileName Cy3 Cy5
1391 1391.spot wt1 mu1
1392 1392.spot mu1 wt1
1340 1340.spot wt2 mu1
1341 1341.spot mu1 wt2
1395 1395.spot wt3 mu1
1396 1396.spot mu1 wt3
1393 1393.spot wt1 mu2
1394 1394.spot mu2 wt1
1371 1371.spot wt2 mu2
1372 1372.spot mu2 wt2
1338 1338.spot wt3 mu2
1339 1339.spot mu2 wt3
1387 1387.spot wt1 mu3
1388 1388.spot mu3 wt1
1399 1399.spot wt2 mu3
1390 1390.spot mu3 wt2
1397 1397.spot wt3 mu3
1398 1398.spot mu3 wt3
```

The comparison of interest is the average difference between the mutant and wild type mice. `duplicateCorrelation()` could not be used here because the arrays do not group neatly into biological replicate groups. In any case, with six arrays on each mouse it is much safer and more conservative to fit an effect for each mouse. We could proceed as

```
> design <- modelMatrix(targets, ref="wt1")
> design <- cbind(Dye=1, design)
> colnames(design)
```

```
[1] "Dye" "mu1" "mu2" "mu3" "wt2" "wt3"
```

The above code treats the first wild-type mouse as a baseline reference so that columns of the design matrix represent the difference between each of the other mice and wt1. The design matrix also includes an intercept term which represents the dye effect of cy5 over cy3 for each gene. If you don't wish to allow for a dye effect, the second line of code can be omitted.

```
> fit <- lmFit(MA, design)
> cont.matrix <- makeContrasts(mu1+mu2+mu3-wt2-wt3)/3, levels=design)
> fit2 <- contrasts.fit(fit, cont.matrix)
> fit2 <- eBayes(fit2)
> topTable(fit2, adjust="fdr")
```

The contrast defined by the function `makeContrasts` represents the average difference between the mutant and wild-type mice, which is the comparison of interest.

This general approach is applicable to many studies involving biological replicates. Here is another example based on a real example conducted by the WEHI Scott Lab. RNA is collected from four human subjects from the same family, two affected by a leukemia-inducing mutation and two unaffected. Each of the two affected subjects (A1 and A2) is compared with each of the two unaffected subjects (U1 and U2):

FileName	Cy3	Cy5
File1	U1	A1
File2	A1	U2
File3	U2	A2
File4	A2	U1

Our interest is to find genes which are differentially expressed between the affected and unaffected subjects. Although all four arrays compare an affected with an unaffected subject, the four arrays are not independent. We need to take account of the fact that RNA from each subject appears on two different arrays. We do this by fitting a model with a coefficient for each subject and then extracting the contrast between the affected and unaffected subjects:

```
> design <- modelMatrix(targets, ref="U1")
> fit <- lmFit(MA, design)
> cont.matrix <- makeContrasts(AvsU=(A1+A2-U2)/2, levels=design)
> fit2 <- contrasts.fit(fit, cont.matrix)
> fit2 <- eBayes(fit2)
> topTable(fit2, adjust="fdr")
```

10.5 Two Groups

Suppose now that we wish to compare two wild type (Wt) mice with three mutant (Mu) mice using arrays hybridized with a common reference RNA (Ref):

FileName	Cy3	Cy5
File1	Ref	WT
File2	Ref	WT
File3	Ref	Mu
File4	Ref	Mu
File5	Ref	Mu

The interest here is in the comparison between the mutant and wild type mice. There are two major ways in which this comparison can be made. We can

1. create a design matrix which includes a coefficient for the mutant vs wild type difference, or
2. create a design matrix which includes separate coefficients for wild type and mutant mice and then extract the difference as a contrast.

For the first approach, the design matrix should be as follows

```
> design
```

	WTvsREF	MUvsWT
Array1	1	0
Array2	1	0
Array3	1	1
Array4	1	1
Array5	1	1

Here the first coefficient estimates the difference between wild type and the reference for each probe while the second coefficient estimates the difference between mutant and wild type. For those not familiar with model matrices in linear regression, it can be understood in the following way. The matrix indicates which coefficients apply to each array. For the first two arrays the fitted values will be just the **WTvsREF** coefficient, which is correct. For the remaining arrays the fitted values will be **WTvsREF + MUvsWT**, which is equivalent to mutant vs reference, also correct. For reasons that will be apparent later, this is sometimes called the *treatment-contrasts* parametrization. Differentially expressed genes can be found by

```
> fit <- lmFit(MA, design)
> fit <- eBayes(fit)
> topTable(fit, coef="MUvsWT", adjust="fdr")
```

There is no need here to use `contrasts.fit()` because the comparison of interest is already built into the fitted model. This analysis is analogous to the classical *pooled two-sample t-test* except that information has been borrowed between genes.

For the second approach, the design matrix should be

	WT	MU
Array1	1	0
Array2	1	0
Array3	0	1
Array4	0	1
Array5	0	1

The first coefficient now represents wild-type vs the reference and the second represents mutant vs the reference. Our comparison of interest is the difference between these two coefficients. We will call this the *group-means* parametrization. Differentially expressed genes can be found by

```
> fit <- lmFit(MA, design)
> cont.matrix <- makeContrasts(MUvsWT=WT-MU, levels=design)
> fit2 <- contrasts.fit(fit, cont.matrix)
> fit2 <- eBayes(fit2)
> topTable(fit2, adjust="fdr")
```

The results will be exactly the same as for the first approach.

The design matrix can be constructed

1. manually,
2. using the limma function `modelMatrix()`, or
3. using the built-in R function `model.matrix()`.

Let `Group` be the factor defined by

```
> Group <- factor(c("WT", "WT", "Mu", "Mu", "Mu"), levels=c("WT", "Mu"))
```

For the first approach, the treatment-contrasts parametrization, the design matrix can be computed by

```
> design <- cbind(WTvsRef=1, MUvsWT=c(0,0,1,1,1))
```

or by

```
> param <- cbind(WTvsRef=c(-1,1,0), MUvsWT=c(0,-1,1))
> rownames(param) <- c("Ref", "WT", "Mu")
> design <- modelMatrix(targets, parameters=param)
```

or by

```
> design <- model.matrix(~Group)
> colnames(design) <- c("WTvsRef", "MUvsWT")
```

all of which produce the same result. For the second approach, the group-means parametrization, the design matrix can be computed by

```
> design <- cbind(WT=c(1,1,0,0,0), MU=c(0,0,1,1,1))
```

or by

```
> param <- cbind(WT=c(-1,1,0),MU=c(-1,0,1))
> rownames(param) <- c("Ref","WT","Mu")
> design <- modelMatrix(targets, parameters=param)
```

or by

```
> design <- model.matrix(~0+Group)
> colnames(design) <- c("WT","Mu")
```

all of which again produce the same result.

10.6 Two Groups: Affymetrix

Suppose now that we wish to compare two wild type (Wt) mice with three mutant (Mu) mice using Affymetrix arrays or any other single-channel array technology:

FileName	Target
File1	WT
File2	WT
File3	Mu
File4	Mu
File5	Mu

Everything is exactly as in the previous section, except that the function `modelMatrix()` would not be used. We can either

1. create a design matrix which includes a coefficient for the mutant vs wild type difference, or
2. create a design matrix which includes separate coefficients for wild type and mutant mice and then extract the difference as a contrast.

For the first approach, the treatment-contrasts parametrization, the design matrix should be as follows:

```
> design

      WT MUvsWT
Array1  1      0
Array2  1      0
Array3  1      1
Array4  1      1
Array5  1      1
```

Here the first coefficient estimates the mean log-expression for wild type mice and plays the role of an intercept. The second coefficient estimates the difference between mutant and wild type. Differentially expressed genes can be found by

```
> fit <- lmFit(eset, design)
> fit <- eBayes(fit)
> topTable(fit, coef="MUvsWT", adjust="fdr")
```

where `eset` is an `exprSet` or `matrix` object containing the log-expression values. For the second approach, the design matrix should be

```

      WT MU
Array1  1  0
Array2  1  0
Array3  0  1
Array4  0  1
Array5  0  1

```

Differentially expressed genes can be found by

```

> fit <- lmFit(eset, design)
> cont.matrix <- makeContrasts(MUvsWT=WT-MU, levels=design)
> fit2 <- contrasts.fit(fit, cont.matrix)
> fit2 <- eBayes(fit2)
> topTable(fit2, adjust="fdr")

```

For the first approach, the treatment-contrasts parametrization, the design matrix can be computed by

```
> design <- cbind(WT=1,MUvsWT=c(0,0,1,1,1))
```

or by

```

> design <- model.matrix(~Group)
> colnames(design) <- c("WT", "MUvsWT")

```

For the second approach, the group-means parametrization, the design matrix can be computed by

```
> design <- cbind(WT=c(1,1,0,0,0),MU=c(0,0,1,1,1))
```

or by

```

> design <- model.matrix(~0+Group)
> colnames(design) <- c("WT", "MU")

```

10.7 Factorial Designs

Factorial designs are those where more than one experimental dimension is being varied and each combination of treatment conditions is observed. Suppose that cells are extracted from wild type and mutant mice and these cells are either stimulated (S) or unstimulated (U). RNA from the treated cells is then extracted and hybridized to a microarray. We will assume for simplicity that the arrays are single-color arrays such as Affymetrix. Consider the following targets frame:

FileName	Strain	Treatment
File1	WT	U
File2	WT	S
File3	Mu	U
File4	Mu	S
File5	Mu	S

The two experimental dimensions or *factors* here are Strain and Treatment. Strain specifies the genotype of the mouse from which the cells are extracted and Treatment specifies whether the cells are stimulated or not. All four combinations of Strain and Treatment are observed, so this is a factorial design. It will be convenient for us to collect the Strain/Treatment combinations into one vector as follows:

```
> TS <- paste(targets$Strain, targets$Treatment, sep=".")
> TS

[1] "WT.U" "WT.S" "Mu.U" "Mu.S" "Mu.S"
```

It is especially important with a factorial design to decide what are the comparisons of interest. We will assume here that the experimenter is interested in

1. which genes respond to stimulation in wild-type cells,
2. which genes respond to stimulation in mutant cells, and
3. which genes respond differently in mutant compared to wild-type cells.

as these are the questions which are most usually relevant in a molecular biology context. The first of these questions relates to the WT.S vs WT.U comparison and the second to Mu.S vs Mu.U. The third relates to the difference of differences, i.e., $(\text{Mu.S} - \text{Mu.U}) - (\text{WT.S} - \text{WT.U})$, which is called the *interaction* term.

We describe first a simple way to analyse this experiment using limma commands in a similar way to that in which two-sample designs were analyzed. Then we will go on to describe the more classical statistical approaches using factorial model formulas. All the approaches considered are equivalent and yield identical bottom-line results. The most basic approach is to fit a model with a coefficient for each of the four factor combinations and then to extract the comparisons of interest as contrasts:

```
> TS <- factor(TS, levels=c("WT.U", "WT.S", "Mu.U", "Mu.S"))
> design <- model.matrix(~0+TS)
> colnames(design) <- levels(TS)
> fit <- lmFit(eset, design)
```

This fits a model with four coefficients corresponding to WT.U, WT.S, Mu.U and Mu.S respectively. Our three contrasts of interest can be extracted by

```
> cont.matrix <- makeContrasts(
+   WT.SvsU=WT.S-WT.U,
+   Mu.SvsU=Mu.S-Mu.U,
+   Diff=(Mu.S-Mu.U)-(WT.S-WT.U),
+   levels=design)
> fit2 <- contrasts.fit(fit, cont.matrix)
> fit2 <- eBayes(fit2)
```

We can use `topTable()` to look at lists of differentially expressed genes for each of three contrasts, or else

```
> results <- decideTests(fit2)
> vennDiagram(results)
```

to look at all three contrasts simultaneously.

The analysis of factorial designs has a long history in statistics and a system of factorial *model formulas* has been developed to facilitate the analysis of complex designs. It is important to understand though that the above three molecular biology questions do not correspond to any of the usual parametrizations used in statistics for factorial designs. Suppose for example that we proceed in the usual statistical way,

```
> Strain <- factor(targets$Strain, levels=c("WT", "Mu"))
> Treatment <- factor(targets$Treatment, levels=c("U", "S"))
> design <- model.matrix(~Strain*Treatment)
```

This creates a design matrix which defines four coefficients with the following interpretations:

Coefficient	Comparison	Interpretation
Intercept	WT.U	Baseline level of unstimulated WT
StrainMu	Mu.U-WT.U	Difference between unstimulated strains
TreatmentS	WT.S-WT.U	Stimulation effect for WT
StrainMu:TreatmentS	(Mu.S-Mu.U)-(WT.S-WT.U)	Interaction

This is called the *treatment-contrast* parametrization. Notice that one of our comparisons of interest, Mu.S-Mu.U, is not represented and instead the comparison Mu.U-WT.U, which might not be of direct interest, is included. We need to use contrasts to extract all the comparisons of interest:

```
> fit <- lmFit(eset, design)
> cont.matrix <- cbind(WT.SvsU=c(0,0,1,0), Mu.SvsU=c(0,0,1,1), Diff=c(0,0,0,1))
> fit2 <- contrasts.fit(fit, cont.matrix)
> fit2 <- eBayes(fit2)
```

This extracts the WT stimulation effect as the third coefficient and the interaction as the fourth coefficient. The mutant stimulation effect is extracted as the sum of the third and fourth coefficients of the original model. This analysis yields exactly the same results as the previous analysis.

An even more classical statistical approach to the factorial experiment would be to use the *sum to zero* parametrization. In R this is achieved by

```
> contrasts(Strain) <- contr.sum(2)
> contrasts(Treatment) <- contr.sum(2)
> design <- model.matrix(~Strain*Treatment)
```

This defines four coefficients with the following interpretations:

Coefficient	Comparison	Interpretation
Intercept	(WT.U+WT.S+Mu.U+Mu.S)/4	Grand mean
Strain1	(WT.U+WT.S-Mu.U-Mu.S)/4	Strain main effect
Treatment1	(WT.U-WT.S+Mu.U-Mu.S)/4	Treatment main effect
Strain1:Treatment1	(WT.U-WT.S-Mu.U+Mu.S)/4	Interaction

This parametrization has many appealing mathematical properties and is the classical parametrization used for factorial designs in much experimental design theory. However it defines only one coefficient which is directly of interest to us, namely the interaction. Our three contrasts of interest could be extracted using

```
> fit <- lmFit(eset, design)
> cont.matrix <- cbind(WT.SvsU=c(0,0,-2,-2),Mu.SvsU=c(0,0,-2,2),Diff=c(0,0,0,4))
> fit2 <- contrasts.fit(fit, cont.matrix)
> fit2 <- eBayes(fit2)
```

The results will be identical to those for the previous two approaches.

The three approaches described here for the 2×2 factorial problem are equivalent and differ only in the parametrization chosen for the linear model. The three fitted model objects `fit` will differ only in the `coefficients` and associated components. The residual standard deviations `fit$sigma`, residual degrees of freedom `fit$df.residual` and all components of `fit2` will be identical for the three approaches. Since the three approaches are equivalent, users are free to choose whichever one is most convenient or intuitive.

11 Statistics for Differential Expression

A number of summary statistics are computed by the `eBayes()` function for each gene and each contrast. The M-value (**M**) is the log2-fold change, or sometimes the log2-expression level, for that gene. The A-value (**A**) is the the average expression level for that gene across all the arrays and channels. The moderated t-statistic (**t**) is the ratio of the M-value to its standard error. This has the same interpretation as an ordinary t-statistic except that the standard errors have been moderated across genes, effectively borrowing information from the ensemble of genes to aid with inference about each individual gene. The ordinary t-statistics are not usually required or recommended, but they can be recovered by

```
> tstat.ord <- fit$coef / fit$stdev.unscaled / fit$sigma
```

after fitting a linear model. The ordinary t-statistic is on `fit$df.residual` degrees of freedom while the moderated t-statistic is on `fit$df.residual+fit$df.prior` degrees of freedom.

The p-value (**p-value**) is obtained from the moderated t-statistic, usually after some form of adjustment for multiple testing. The most popular form of adjustment is “fdr” which is Benjamini and Hochberg’s method to control the false discovery rate. The meaning of the adjusted p-value is as follows. If you select all genes with p-value below a given value, say 0.05, as differentially expression, then the expected proportion of false discoveries in the selected group should be less than that value, in this case less than 5%.

The B-statistic (**lods** or **B**) is the log-odds that that gene is differentially expressed. Suppose for example that $B=1.5$. The odds of differential expression is $\exp(1.5)=4.48$, i.e., about four and a half to one. The probability that the gene is differentially expressed is $4.48/(1+4.48)=0.82$, i.e., the probability is about 82% that this gene is differentially expressed. A B-statistic of zero corresponds to a 50-50 chance that the gene is differentially expressed. The B-statistic is automatically adjusted for multiple testing by assuming that 1%

of the genes, or some other percentage specified by the user, are expected to be differentially expressed. If there are no missing values in your data, then the moderated t and B statistics will rank the genes in exactly the same order. Even you do have spot weights or missing data, the p-values and B-statistics will usually provide a very similar ranking of the genes.

Please keep in mind that the moderated t-statistic p-values and the B-statistic probabilities depend on various sorts of mathematical assumptions which are never exactly true for microarray data. The B-statistics also depend on a prior guess for the proportion of differentially expressed genes. Therefore they are intended to be taken as a guide rather than as a strict measure of the probability of differential expression. Of the three statistics, the moderated-t, the associated p-value and the B-statistics, we usually base our gene selections on the p-value. All three measures are closely related, but the moderated-t and its p-value do not require a prior guess for the number of differentially expressed genes.

The above mentioned statistics are computed for every contrast for each gene. The `eBayes()` function computes one more useful statistic. The moderated F-statistic (F) combines the t-statistics for all the contrasts into an overall test of significance for that gene. The moderated F-statistic tests whether any of the contrasts are non-zero for that gene, i.e., whether that gene is differentially expressed on any contrast. The moderated-F has numerator degrees of freedom equal to the number of contrasts and denominator degrees of freedom the same as the moderated-t. Its p-value is stored as `fit$F.p.value`. It is similar to the ordinary F-statistic from analysis of variance except that the denominator mean squares are moderated across genes.

In a complex experiment with many contrasts, it may be desirable to select genes firstly on the basis of their moderated F-statistics, and subsequently to decide which of the individual contrasts are significant for the selected genes. This cuts down on the number of tests which need to be conducted and therefore on the amount of adjustment for multiple testing. The function `decideTests()` with `method="nestedF"` is able to conduct such tests.

A warning on distributional assumptions. In the microarray context it is difficult to verify distributional assumptions, such as normality of the M-values, that the p-values are based on. This is a limitation of all model-based methods for microarray data. This means that the p-values given are intended as a guide only. Also beware that the Benjamini and Hochberg method used to control the false discovery rate does assume that the t-statistics for different probes are independent, whereas the t-statistics for different probes are actually somewhat dependent as a result of being based on observations made on the same set of arrays. Reiner et al (2003) have argued that the Benjamini and Hochberg approach is actually quite stable with respect to dependence between the probes, but there remains no theoretical results to support this.

12 Data Objects in Limma

There are four main types of data objects created and used in limma:

RGList. Red-Green list. A class used to store raw intensities as they are read in from an image analysis output file, usually by `read.maimages()`.

MAList. Intensities converted to M-values and A-values, i.e., to with-spot and whole-spot contrasts on the log-scale. Usually created from an **RGList** using **MA.RG()** or **normalizeWithinArrays()**. Objects of this class contain one row for each spot. There may be more than one spot and therefore more than one row for each probe.

MArrayLM. Store the result of fitting gene-wise linear models to the normalized intensities or log-ratios. Usually created by **lmFit**. Objects of this class normally contain one row for each unique probe.

TestResults. Store the results of testing a set of contrasts equal to zero for each probe. Usually created by **decideTests**. Objects of this class normally contain one row for each unique probe.

For those who are familiar with matrices in R, all these objects are designed to obey many analogies with matrices. In the case of **RGList** and **MAList**, rows correspond to spots and columns to arrays. In the case of **MArrayLM**, rows correspond to unique probes and columns to parameters or contrasts. The functions **summary**, **dim**, **length**, **ncol**, **nrow**, **dimnames**, **rownames**, **colnames** have methods for these classes. For example

```
> dim(RG)

[1] 11088 4
```

shows that the **RGList** object **RG** contains data for 11088 spots and 4 arrays.

```
> colnames(RG)
```

will give the names of the filenames or arrays in the object, while if **fit** is an **MArrayLM** object then

```
> colnames(fit)
```

would give the names of the coefficients in the linear model fit.

Objects of any of these classes may be subsetted, so that **RG[,j]** means the data for array **j** and **RG[i,]** means the data for probes indicated by the index **i**. Multiple data objects may be combined using **cbind**, **rbind** or **merge**. Hence

```
> RG1 <- read.maimages(files[1:2], source="genepix")
> RG2 <- read.maimages(files[3:5], source="genepix")
> RG <- cbind(RG1, RG2)
```

is equivalent to

```
> RG <- read.maimages(files[1:5], source="genepix")
```

Alternatively, if control status has been set in the an **MAList** object then

```
> i <- MA$genes$Status=="Gene"
> MA[i,]
```

might be used to eliminate control spots from the data object prior to fitting a linear model.

13 Case Studies

13.1 Swirl Zebrafish: A Single-Sample Experiment

In this section we consider a case study in which two RNA sources are compared directly on a set of replicate or dye-swap arrays. The case study includes reading in the data, data display and exploration, as well as normalization and differential expression analysis. The analysis of differential expression is analogous to a classical one-sample test of location for each gene.

In this example we assume that the data is provided as a GAL file called `fish.gal` and raw SPOT output files and that these files are in the current working directory.

```
> dir()
[1] "fish.gal"          "swirl.1.spot"      "swirl.2.spot"      "swirl.3.spot"      "swirl.4.spot"
[6] "SwirlSample.txt"
```

Background. The experiment was carried out using zebrafish as a model organism to study the early development in vertebrates. Swirl is a point mutant in the BMP2 gene that affects the dorsal/ventral body axis. The main goal of the Swirl experiment is to identify genes with altered expression in the Swirl mutant compared to wild-type zebrafish.

The hybridizations. Two sets of dye-swap experiments were performed making a total of four replicate hybridizations. Each of the arrays compares RNA from swirl fish with RNA from normal (“wild type”) fish. The experimenters have prepared a tab-delimited targets file called `SwirlSamples.txt` which describes the four hybridizations:

```
> library(limma)
> targets <- readTargets("SwirlSample.txt")
> targets
```

SlideNumber	FileName	Cy3	Cy5	Date
1	81 swirl.1.spot	swirl	wild type	2001/9/20
2	82 swirl.2.spot	wild type	swirl	2001/9/20
3	93 swirl.3.spot	swirl	wild type	2001/11/8
4	94 swirl.4.spot	wild type	swirl	2001/11/8

We see that slide numbers 81, 82, 93 and 94 were used to make the arrays. On slides 81 and 93, swirl RNA was labelled with green (Cy3) dye and wild type RNA was labelled with red (Cy5) dye. On slides 82 and 94, the labelling was the other way around.

Each of the four hybridized arrays was scanned on an Axon scanner to produce a TIFF image, which was then processed using the image analysis software SPOT. The data from the arrays are stored in the four output files listed under `FileName`. Now we read the intensity data into an `RGList` object in R. The default for SPOT output is that `Rmean` and `Gmean` are used as foreground intensities and `morphR` and `morphG` are used as background intensities:

```
> RG <- read.maimages(targets$FileName, source="spot")
Read swirl.1.spot
Read swirl.2.spot
Read swirl.3.spot
```

```

Read swirl.4.spot
> RG
An object of class "RGList"

```

The arrays. The microarrays used in this experiment were printed with 8448 probes (spots), including 768 control spots. The array printer uses a print head with a 4x4 arrangement of print-tips and so the microarrays are partitioned into a 4x4 grid of tip groups. Each grid consists of 22x24 spots that were printed with a single print-tip. The gene name associated with each spot is recorded in a GenePix array list (GAL) file:

```

> RG$genes <- readGAL("fish.gal")
> RG$genes[1:30,]

```

	Block	Row	Column	ID	Name
1	1	1	1	control	geno1

The 4x4x22x24 print layout also needs to be set. The easiest way to do this is to infer it from the GAL file:

```
> RG$printer <- getLayout(RG$genes)
```

Image plots. It is interesting to look at the variation of background values over the array. Consider image plots of the red and green background for the first array:

```
> imageplot(log2(RG$Rb[,1]), RG$printer, low="white", high="red")
> imageplot(log2(RG$Gb[,1]), RG$printer, low="white", high="green")
```

Image plot of the un-normalized log-ratios or M-values for the first array:

```
> MA <- normalizeWithinArrays(RG, method="none")
> imageplot(MA$M[,1], RG$printer, zlim=c(-3,3))
```

The `imageplot` function lies the slide on its side, so the first print-tip group is bottom left in this plot. We can see a red streak across the middle two grids of the 3rd row caused by a scratch or dust on the array. Spots which are affected by this artefact will have suspect M-values. The streak also shows up as darker regions in the background plots.

MA-plots. An MA-plot plots the log-ratio of R vs G against the overall intensity of each spot. The log-ratio is represented by the M-value, $M = \log_2(R) - \log_2(G)$, and the overall intensity by the A-value, $A = (\log_2(R) + \log_2(G))/2$. Here is the MA-plot of the un-normalized values for the first array:

```
> plotMA(MA)
```

The red streak seen on the image plot can be seen as a line of spots in the upper right of this plot. Now we plot the individual MA-plots for each of the print-tip groups on this array, together with the loess curves which will be used for normalization:

```
> plotPrintTipLoess(MA)
```

Normalization. Print-tip loess normalization:

```
> MA <- normalizeWithinArrays(RG)
> plotPrintTipLoess(MA)
```

We have normalized the M-values with each array. A further question is whether normalization is required between the arrays. The following plot shows overall boxplots of the M-values for the four arrays.

```
> boxplot(MA$M~col(MA$M),names=colnames(MA$M))
```

There is some evidence that the different arrays have different spreads of M-values, so we will scale normalize between the arrays.

```
> MA <- normalizeBetweenArrays(MA)
> boxplot(MA$M~col(MA$M), names=colnames(MA$M))
```

Linear model. Now estimate the average M-value for each gene. We do this by fitting a simple linear model for each gene. The negative numbers in the design matrix indicate the dye-swaps.

```

> design <- c(-1,1,-1,1)
> fit <- lmFit(MA,design)
> fit

```

In the above fit object, `coefficients` is the average M-value for each gene and `sigma` is the sample standard deviations for each gene. Ordinary t-statistics for comparing mutant to wt could be computed by

```
> ordinary.t <- fit$coef / fit$stdev.unscaled / fit$sigma
```

We prefer though to use empirical Bayes moderated t-statistics which are computed below.

Now create an MA-plot of the average M and A-values for each gene.

```
> plotMA(fit)
> abline(0,0,col="blue")
```

Empirical Bayes analysis. We will now go on and compute empirical Bayes statistics for differential expression. The moderated t-statistics use sample standard deviations which have been shrunk towards a pooled standard deviation value.

```
> fit <- eBayes(fit)
> qqf(fit$t,df=fit$df.prior+fit$df.residual,pch=16,cex=0.2)
> abline(0,1)
```

Visually there seems to be plenty of genes which are differentially expressed. We will obtain a summary table of some key statistics for the top genes.

```
> options(digits=3)
> topTable(fit,number=30,adjust="fdr")
```

The top gene is BMP2 which is significantly down-regulated in the Swirl zebrafish, as it should be because the Swirl fish are mutant in this gene. Other positive controls also appear in the top 30 genes in terms.

In the table, *t* is the empirical Bayes moderated t-statistic, the corresponding P-values have been adjusted to control the false discovery rate and *B* is the empirical Bayes log odds of differential expression.

```

> top30 <- ord[1:30]
> text(fit$Amean[top30],fit$coef[top30],labels=fit$genes[top30,"Name"],cex=0.8,col="blue")
```

13.2 ApoAI Knockout Data: A Two-Sample Experiment

In this section we consider a case study where two RNA sources are compared through a common reference RNA. The analysis of the log-ratios involves a two-sample comparison of means for each gene.

In this example we assume that the data is available as an RGList in the data file `ApoAI.RData`.

Background. The data is from a study of lipid metabolism by Callow et al (2000). The apolipoprotein AI (ApoAI) gene is known to play a pivotal role in high density lipoprotein (HDL) metabolism. Mice which have the ApoAI gene knocked out have very low HDL cholesterol levels. The purpose of this experiment is to determine how ApoAI deficiency affects the action of other genes in the liver, with the idea that this will help determine the molecular pathways through which ApoAI operates.

Hybridizations. The experiment compared 8 ApoAI knockout mice with 8 normal C57BL/6 ("black six") mice, the control mice. For each of these 16 mice, target mRNA was obtained from liver tissue and labelled using a Cy5 dye. The RNA from each mouse was hybridized to a separate microarray. Common reference RNA was labelled with Cy3 dye and used for all the arrays. The reference RNA was obtained by pooling RNA extracted from the 8 control mice.

Number of arrays	Red	Green
8	Normal “black six” mice	Pooled reference
8	ApoAI knockout	Pooled reference

This is an example of a single comparison experiment using a common reference. The fact that the comparison is made by way of a common reference rather than directly as for the swirl experiment makes this, for each gene, a two-sample rather than a single-sample setup.

```

> library(limma)

> load("ApoAI.RData")
> objects()
[1] "RG"
> names(RG)
[1] "R" "G" "Rb" "Gb" "printer" "genes" "targets"
> RG$targets
      FileName  Cy3      Cy5

k7 a1kok7.spot Pool ApoAI-/-
k8 a1kok8.spot Pool ApoAI-/-
> MA <- normalizeWithinArrays(RG)
> cols <- MA$targets$Cy5
> cols[cols=="C57BL/6"] <- "blue"
> cols[cols=="ApoAI-/-"] <- "yellow"
> boxplot(MA$M~col(MA$M),names=rownames(MA$targets),col=cols,xlab="Mouse",ylab="M-values")

```

Since the common reference here is a pool of the control mice, we expect to see more differences from the pool for the knock-out mice than for the control mice. In terms of the above plot, this should translate into a wider range of M-values for the knock-out mice arrays than for

the control arrays, and we do see this. Since the different arrays are not expected to have the same range of M-values, between-array scale normalization of the M-values is not appropriate here.

Now we can go on to estimate the fold change between the two groups. In this case the design matrix has two columns. The coefficient for the second column estimates the parameter of interest, the log-ratio between knockout and control mice.

Notice that the top gene is ApoAI itself which is heavily down-regulated. Theoretically the M-value should be minus infinity for ApoAI because it is the knockout gene. Several of the other genes are closely related. The top eight genes here were confirmed by independent assay subsequent to the microarray experiment to be differentially expressed in the knockout versus the control line.

```
> volcanoplot(fit,coef=2,highlight=8,names=fit$genes$NAME,main="KO vs Control")
```

13.3 Ecoli Lrp Data: Affymetrix Data with Two Targets

The data are from experiments reported in Hung et al (2002) and are available from the www site <http://visitor.ics.uci.edu/genex/cybert/tutorial/index.html>. The data is also available from the ecoliLeucine data package available from the Bioconductor www site under "Experimental Data". Hung et al (2002) state that

The purpose of the work presented here is to identify the network of genes that are differentially regulated by the global *E. coli* regulatory protein, leucine-responsive regulatory protein (Lrp), during steady state growth in a glucose supplemented minimal salts medium. Lrp is a DNA-binding protein that has been reported to affect the expression of approximately 55 genes.

Gene expression in two *E. coli* bacteria strains, labelled lrp+ and lrp-, were compared using eight Affymetrix ecoli chips, four chips each for lrp+ and lrp-.

The following code assumes that the data files for the eight chips are in your current working directory.

```
> dir()
[1] "Ecoli.CDF"          "nolrp_1.CEL"      "nolrp_2.CEL"
[4] "nolrp_3.CEL"        "nolrp_4.CEL"      "wt_1.CEL"
[7] "wt_2.CEL"           "wt_3.CEL"         "wt_4.CEL"
```

The data is read and normalized using the `affy` package. The package `ecolicdf` must also be installed, otherwise the `rma()` function will attempt to download and install it for you—without giving you the opportunity to veto the download.

```
> library(limma)
> library(affy)
Welcome to Bioconductor
  Vignettes contain introductory material. To view,
  simply type: openVignette()
  For details on reading vignettes, see
  the openVignette help page.
> Data <- ReadAffy()
> eset <- rma(Data)
Background correcting
Normalizing
Calculating Expression
> pData(eset)
      sample
nolrp_1.CEL    1
nolrp_2.CEL    2
nolrp_3.CEL    3
nolrp_4.CEL    4
wt_1.CEL       5
wt_2.CEL       6
wt_3.CEL       7
wt_4.CEL       8
```

Now we consider differential expression between the `lrp+` and `lrp-` strains.

```
> strain <- c("lrp-", "lrp-", "lrp-", "lrp-", "lrp+", "lrp+", "lrp+", "lrp+")
> design <- model.matrix(~factor(strain))
> colnames(design) <- c("lrp-", "lrp+vs-")
> design
  lrp- lrp+vs-
1    1      0
2    1      0
3    1      0
4    1      0
5    1      1
6    1      1
7    1      1
8    1      1
attr(,"assign")
[1] 0 1
attr(,"contrasts")
attr(,"contrasts")$"factor(strain)"
[1] "contr.treatment"
```

The first coefficient measures \log_2 -expression of each gene in the lrp- strain. The second coefficient measures the \log_2 -fold change of lrp+ over lrp-, i.e., the log-fold change induced by lrp.

```
> fit <- lmFit(eset, design)
> fit <- eBayes(fit)
> options(digits=2)
> topTable(fit, coef=2, n=40, adjust="fdr")
```

The column M gives the \log_2 -fold change while the column A gives the average \log_2 -intensity for the probe-set. Positive M-values mean that the gene is up-regulated in lrp+, negative

values mean that it is repressed.

It is interesting to compare this table with Tables III and IV in Hung et al (2002). Note that the top-ranked gene is an intergenic region (IG) tRNA gene. The knock-out gene itself is in position four. Many of the genes in the above table, including the ser, glt, liv, opp, lys, ilv and fim families, are known targets of lrp.

13.4 Estrogen Data: A 2x2 Factorial Experiment with Affymetrix Arrays

This data is from the estrogen package on Bioconductor. A subset of the data is also analysed in the factDesign package vignette. To repeat this case study you will need to have the R packages affy, estrogen and hgu95av2cdf installed.

The data gives results from a 2x2 factorial experiment on MCF7 breast cancer cells using Affymetrix HGU95av2 arrays. The factors in this experiment were estrogen (present or absent) and length of exposure (10 or 48 hours). The aim of the study is to identify genes which respond to estrogen and to classify these into early and late responders. Genes which respond early are putative direct-target genes while those which respond late are probably downstream targets in the molecular pathway.

First load the required packages:

```
> library(limma)
> library(affy)
Welcome to Bioconductor
  Vignettes contain introductory material. To view,
  simply type: openVignette()
  For details on reading vignettes, see
  the openVignette help page.
> library(hgu95av2cdf)
```

The data files are contained in the `extdata` directory of the estrogen package:

```
> datadir <- file.path(.find.package("estrogen"), "extdata")
> dir(datadir)
[1] "00Index"      "bad.cel"      "high10-1.cel" "high10-2.cel" "high48-1.cel"
[6] "high48-2.cel" "low10-1.cel"  "low10-2.cel"  "low48-1.cel"  "low48-2.cel"
[11] "phenoData.txt"
```

The targets file is called `phenoData.txt`. We see there are two arrays for each experimental condition, giving a total of 8 arrays.

```
> targets <- readTargets("phenoData.txt", path=datadir, sep="", row.names="filename")
> targets
```

	filename	estrogen	time.h
low10-1	low10-1.cel	absent	10
low10-2	low10-2.cel	absent	10
high10-1	high10-1.cel	present	10
high10-2	high10-2.cel	present	10
low48-1	low48-1.cel	absent	48
low48-2	low48-2.cel	absent	48

```
high48-1 high48-1.cel present 48
high48-2 high48-2.cel present 48
```

Now read the cel files into an AffyBatch object and normalize using the `rma()` function from the affy package:

```
> ab <- ReadAffy(filename=targets$filename, celfile.path=datadir)
> eset <- rma(ab)
Background correcting
Normalizing
Calculating Expression
```

There are many ways to construct a design matrix for this experiment. Given that we are interested in the early and late estrogen responders, we can choose a parametrization which includes these two contrasts.

```
> treatments <- factor(c(1,1,2,2,3,3,4,4),labels=c("e10","E10","e48","E48"))
> contrasts(treatments) <- cbind(Time=c(0,0,1,1),E10=c(0,1,0,0),E48=c(0,0,0,1))
> design <- model.matrix(~treatments)
> colnames(design) <- c("Intercept","Time","E10","E48")
```

The second coefficient picks up the effect of time in the absence of estrogen. The third and fourth coefficients estimate the \log_2 -fold change for estrogen at 10 hours and 48 hours respectively.

```
> fit <- lmFit(eset,design)
```

We are only interested in the estrogen effects, so we choose a contrast matrix which picks these two coefficients out:

```
> cont.matrix <- cbind(E10=c(0,0,1,0),E48=c(0,0,0,1))
> fit2 <- contrasts.fit(fit, cont.matrix)
> fit2 <- eBayes(fit2)
```

We can examine which genes respond to estrogen at either time using the moderated F-statistics on 2 degrees of freedom. The moderated F p-value is stored in the component `fit2$F.p.value`.

What p-value cutoff should be used? One way to decide which changes are significant for each gene would be to use Benjamini and Hochberg's method to control the false discovery rate across all the genes and both tests:

```
> results <- decideTests(fit2, method="global")
```

Another method would be to adjust the F-test p-values rather than the t-test p-values:

```
> results <- decideTests(fit2, method="nestedF")
```

Here we use a more conservative method which depends far less on distributional assumptions, which is to make use of control and spike-in probe-sets which theoretically should not be differentially-expressed. The smallest p-value amongst these controls turns out to be about 0.00014:

```
> i <- grep("AFFX",geneNames(eset))
> summary(fit2$F.p.value[i])
      Min.   1st Qu.   Median     Mean   3rd Qu.    Max.
0.0001391 0.1727000 0.3562000 0.4206000 0.6825000 0.9925000
```

So a cutoff p-value of 0.0001, say, would conservatively avoid selecting any of the control probe-sets as differentially expressed:

```
> results <- classifyTestsF(fit2, p.value=0.0001)
> summary(results)
```

	E10	E48
-1	40	76
0	12469	12410
1	116	139

```
> table(E10=results[,1],E48=results[,2])
```

		E48		
E10	-1	0	1	
-1	29	11	0	
0	47	12370	52	
1	0	29	87	

```
> vennDiagram(results,include="up")
```

```
> vennDiagram(results,include="down")
```

We see that 87 genes were up regulated at both 10 and 48 hours, 29 only at 10 hours and 52 only at 48 hours. Also, 29 genes were down-regulated throughout, 11 only at 10 hours and 47 only at 48 hours. No genes were up at one time and down at the other.

`topTable` gives a detailed look at individual genes. The leading genes are clearly significant, even using the default p-value adjustment method, which is the highly conservative Holm's method.

```
> options(digits=3)
> topTable(fit2,coef="E10",n=20)
```

13.5 Weaver Mutant Data: A 2x2 Factorial Experiment with Two-Color Data

This case study considers a more involved analysis in which the sources of RNA have a factorial structure.

Background. This is a case study examining the development of certain neurons in wild-type and weaver mutant mice from Diaz et al (2002). The weaver mutant affects cerebellar granule neurons, the most numerous cell-type in the central nervous system. Weaver mutant mice are characterized by a weaving gait. Granule cells are generated in the first postnatal week in the external granule layer of the cerebellum. In normal mice, the terminally differentiated granule cells migrate to the internal granule layer but in mutant mice the cells die before doing so, meaning that the mutant mice have strongly reduced numbers of cells in the internal granule layer. The expression level of any gene which is specific to mature granule cells, or is expressed in response to granule cell derived signals, is greatly reduced in the mutant mice.

Tissue dissection and RNA preparation. At each time point (P11 = 11 days postnatal and P21 = 21 days postnatal) cerebella were isolated from two wild-type and two mutant littermates and pooled for RNA isolation. RNA was then divided into aliquots and labelled before hybridizing to the arrays. (This means that different hybridizations are biologically related through using RNA from the same mice, although we will ignore this here. See Yang and Speed (2002) for a detailed discussion of this issue in the context of this experiment.)

Hybridizations. There are four different treatment combinations, P11wt, P11mt, P21wt and P21mt, which might think of as a 2x2 factorial structure. We consider ten arrays in total. There are six arrays comparing the four different RNA sources to a common reference,

which was a pool of RNA from all the time points, and four arrays making direct comparisons between the four treatment combinations.

First read in the data. We assume that the data is an directory called `c:/Weaver`. We first read in the targets frame, and then read the intensity data using file names recorded in the targets file. The data was produced using SPOT image analysis software and is stored in the subdirectory `/spot`. Notice that a spot quality weight function as been set. For these arrays the median spot area is just over 50 pixels. The spot quality function has been set so that any spot with an area less than 50 pixels will get reduced weight, so that a hypothetical spot of zero area would get zero weight.

```
> library(limma)
> setwd("C:/Weaver")
> targets <- readTargets("targets.txt")
> targets
```

	FileName	Tissue	Mouse	Cy5	Cy3
cbmut.3	cbmut.3.spot	Cerebellum	Weaver	P11wt	Pool
cbmut.4	cbmut.4.spot	Cerebellum	Weaver	P11mt	Pool
cbmut.5	cbmut.5.spot	Cerebellum	Weaver	P21mt	Pool
cbmut.6	cbmut.6.spot	Cerebellum	Weaver	P21wt	Pool
cbmut.15	cbmut.15.spot	Cerebellum	Weaver	P21wt	Pool

Setting attributes: values col cex

```
> plotMA(RG,array=9,xlim=c(4,15.5))
```

Here Buffer is an obvious negative control while 18S, GAPDH, Lysine, Threonine and Tubulin are single-gene positive controls, sometime called house-keeping genes. RikenTitration is a titration series of a pool of the entire Riken library, and can be reasonably expected to be non-differentially expressed. CerEstTitration is a titration of a pool of a cerebellum EST library. This will show higher expression in later mutant tissues. The Lys, Phe and Thr series are single-gene titration series which were not spike-in in this case and can be treated as negative controls.

Now normalize the data. Because the Riken titration library, being based on a pool of a large number of non-specific genes, should not be differentially expressed, we up-weight these spots in the print-tip normalization step:

```
> w <- modifyWeights(RG$weights, RG$genes$Status, "RikenTitration", 2)
> MA <- normalizeWithinArrays(RG, weights = w)
```

Now fit a linear model to the data. Because of the composite design, with some common reference arrays and some direct comparison arrays, the simplest method is to use a group-mean parametrization with all RNA samples compared back to the Pool.

```
> design <- modelMatrix(targets, ref = "Pool")
```

Found unique target names:

P11mt P11wt P21mt P21wt Pool

```
> design
```

	P11mt	P11wt	P21mt	P21wt
cbmut.3	0	1	0	0
cbmut.4	1	0	0	0
cbmut.5	0	0	1	0
cbmut.6	0	0	0	1
cbmut.15	0	0	0	1
cbmut.16	0	0	1	0
cb.1	-1	1	0	0
cb.2	1	0	-1	0
cb.3	0	0	1	-1
cb.4	0	-1	0	1

All the control spots are removed before fitting the linear model:

```
> isGene <- MA$genes$Status == "Riken"
> fit <- lmFit(MA[isGene, ], design)
```

We now extract all possible comparisons of interest as contrasts. We look for the mutant vs wt comparisons at 11 and 21 days, the time effects for mutant and wt, and the interaction terms:

```
> cont.matrix <- makeContrasts(
+   WT11.MT11=P11mt-P11wt,
+   WT21.MT21=P21mt-P21wt,
+   WT11.WT21=P21wt-P11wt,
```

```

+ MT11.MT21=P21mt-P11mt,
+ Int=(P21mt-P11mt)-(P11mt-P11wt),
+ levels=design)
> fit2 <- contrasts.fit(fit, cont.matrix)
> fit2 <- eBayes(fit2)

```

Adjustment for multiple testing, with Benjamini and Hochberg's method applied to the F-test p-values across genes with 5% false discovery rate, and nesting F-testing used within contrasts, leads to the following:

```

> results <- decideTests(fit2, method = "nestedF")
> summary(results)

```

	WT11.MT11	WT21.MT21	WT11.WT21	MT11.MT21	Int

1	8	80	113	187	84

There are 187 genes up and 136 genes down in mutant at 21 days vs 11 days. There are 84 genes which respond more up in the mutant than the wt, and 43 genes which respond more down in the mutant than the wt. A heatdiagram shows that the genes are mostly responding in the same direction in the mutant and wt, but to different degrees:

```

> heatDiagram(results, fit2$coef, primary = "Int")

14 Within-Array Replicate Spots

In this section we consider a case study in which all genes (ESTs and controls) are printed more than once on the array. This means that there is both within-array and between-array replication for each gene. The structure of the experiment is therefore essentially a randomized block experiment for each gene. The approach taken here is to estimate a common correlation for all the genes for between within-array duplicates. The theory behind the approach is explained in Smyth, Michaud and Scott (2003). This approach assumes that all genes are replicated the same number of times on the array and that the spacing between the replicates is entirely regular.

14.1 Example. Bob Mutant Data

In this example we assume that the data is available as an RG list.

Background. This data is from a study of transcription factors critical to B cell maturation by Lynn Corcoran and Wendy Dietrich at the WEHI. Mice which have a targeted mutation in the Bob (OBF-1) transcription factor display a number of abnormalities in the B lymphocyte compartment of the immune system. Immature B cells that have emigrated from the bone marrow fail to differentiate into full fledged B cells, resulting in a notable deficit of mature B cells.

Arrays. Arrays were printed with expressed sequence tags (ESTs) from the National Institute of Aging 15k mouse clone library, plus a range of positive, negative and calibration controls. The arrays were printed using a 48 tip print head and 26x26 spots in each tip group. Data from 24 of the tip groups are given here. Every gene (ESTs and controls) was printed twice on each array.

Hybridizations. A retrovirus was used to add Bob back to a Bob deficient cell line. Two RNA sources were compared using 2 dye-swap pairs of microarrays. One RNA source was obtained from the Bob deficient cell line after the retrovirus was used to add GFP ("green fluorescent protein", a neutral protein). The other RNA source was obtained after adding both GFP and Bob protein. RNA from Bob+GFP was labelled with Cy5 in arrays 2 and 4, and with Cy3 in arrays 1 and 4.

```

Although there are only four arrays, we have a total of eight spots for each gene, and more for the controls. Naturally the two M-values obtained from duplicate spots on the same array are highly correlated. The problem is how to make use of the duplicate spots in the best way. The approach taken here is to estimate the spatial correlation between the adjacent spots using REML and then to conduct the usual analysis of the arrays using generalized least squares.

First normalize the data using print-tip loess regression.

```
> MA <- normalizeWithinArrays(RG,layout)
```

Now estimate the spatial correlation. We estimate a correlation term by REML for each gene, and then take a trimmed mean on the atanh scale to estimate the overall correlation. This command takes a lot of time, perhaps as much as an hour for a series of arrays.

```

> cor <- duplicateCorrelation(MA,design,ndups=2) # A slow computation!
> cor$consensus.correlation
[1] 0.571377
> boxplot(cor$all.correlations)

```

```
> fit <- lmFit(MA,design,ndups=2,correlation=0.571377)
> fit <- eBayes(fit)
> topTable(fit,n=30,adjust="fdr")
```

15 Using Objects from the marray Package

The package `marray` is a well known R package for pre-processing of two-color microarray data. `Marray` provides functions for reading, normalization and graphical display of data. `Marray` and `limma` are both descendants of the earlier and path-breaking `SMA` package available from <http://www.stat.berkeley.edu/users/terry/zarray/Software/smacode.html> but `limma` has maintained and built upon the original data structures whereas `marray` has converted to a fully formal data class representation. For this reason, `Limma` is backwardly compatible with `SMA` while `marray` is not.

Normalization functions in `marray` focus on a flexible approach to location and scale normalization of M-values, rather than the within and between-array approach of `limma`. `Marray` provides some normalization methods which are not in `limma` including 2-D loess normalization and print-tip-scale normalization. Although there is some overlap between the normalization functions in the two packages, both providing print-tip loess normalization, the two approaches are largely complementary. `Marray` also provides highly developed functions for graphical display of two-color microarray data.

Read functions in `marray` produce objects of class `marrayRaw` while normalization produces objects of class `marrayNorm`. Objects of these classes may be converted to and from `limma` data objects using the `convert` package. `marrayRaw` objects may be converted to `RGList` objects and `marrayNorm` objects to `MAList` objects using the `as` function. For example, if `Data` is an `marrayNorm` object then

```
> library(convert)
> MA <- as(Data, "MAList")
```

converts to an `MAList` object.

`marrayNorm` objects can also be used directly in `limma` without conversion, and this is generally recommended. If `Data` is an `marrayNorm` object, then

```
> fit <- lmFit(Data, design)
```

fits a linear model to `Data` as it would to an `MAList` object. One difference however is that the `marray` read functions tend to populate the `maW` slot of the `marrayNorm` object with qualitative

spot quality flags rather than with quantitative non-negative weights, as expected by limma. If this is so then one may need

```
> fit <- lmFit(Data, design, weights=NULL)
```

to turn off use of the spot quality weights.

16 Between-Array Normalization of Two-Color Arrays

This section explores some of the methods available for between-array normalization of two-color arrays. A feature which distinguishes most of these methods from within-array normalization is the focus on the individual red and green intensity values rather than merely on the log-ratios. These methods might therefore be called *individual channel* or *separate channel* normalization methods. Individual channel normalization is typically a prerequisite to individual channel analysis methods such as that provided by `lmScFit()`. Further discussion of the issues involved is given by Yang and Thorne (2003). The ApoAI data set from Section 13.2 will be used to illustrate these methods. We assume that the the ApoAI data has been loaded and background corrected as follows:

```
> load("ApoAI.RData")
> RG.b <-backgroundCorrect(RG,method="minimum")
```

This section shows how to reproduce some of the results given in Yang and Thorne (2003).

`plotDensities` displays smoothed empirical densities for the individual green and red channels on all the arrays. Without any normalization there is considerable variation between both channels and between arrays:

```
> plotDensities(RG.b, log.transform=TRUE)
```

After loess normalization of the M-values for each array the red and green distributions become essentially the same for each array, although there is still considerable variation between arrays:

```
> MA.p <- normalizeWithinArrays(RG.b)
> plotDensities(MA.p)
```

Loess normalization doesn't affect the A-values. Applying quantile normalization to the A-values makes the distributions essentially the same across arrays as well as channels:

```
> MA.pAq <- normalizeBetweenArrays(MA.p, method="Aquantile")
> plotDensities(MA.pAq)
```

Applying quantile normalization directly to the individual red and green intensities produces a similar result but is somewhat noisier:

```
> MA.n <- normalizeWithinArrays(RG.b, method="none")
> MA.q <- normalizeWithinArrays(RG.b, method="quantile")
> plotDensities(MA.pq, col="black")
```

There are other between-array normalization methods not explored here. For example `normalizeBetweenArrays` with `method="vsn"` gives an interface to the variance-stabilizing normalization methods of the `vsn` package.

Conventions

Where possible, `limma` tries to use the convention that class names are in upper CamelCase, i.e., the first letter of each word is capitalized, while function names are in lower camelCase, i.e., first word is lowercase. When periods appear in function names, the first word should be an action while the second word is the name of a type of object on which the function acts.

Acknowledgements

Thanks to Yee Hwa Yang and Sandrine Dudoit for the first three data sets. The Swirl zebrafish data were provided by Katrin Wuennenburg-Stapleton from the Ngai Lab at UC Berkeley. Laurent Gautier made the *ecoli*Leucine data set available on Bioconductor. Lynn Corcoran provided the Bob Mutant data.
